This image shows a heparin glycosaminoglycan-modified hydrogel applied to a skin wound, where it sequesters chemokines secreted by immune cells. The hydrogel captured inflammatory chemokines from human venous leg ulcer wound fluid and hastened tissue formation and wound closure in a mouse model of delayed skin healing.

The use of autologous (or syngeneic) cells derived from induced pluripotent stem cells (iPSCs) holds great promise for future clinical use in a wide range of diseases and injuries. It is expected that cell replacement therapies using autologous cells would forego the need for immunosuppression, otherwise required in allogeneic transplantations. However, recent studies have shown the unexpected immune rejection of undifferentiated autologous mouse iPSCs after transplantation. Whether similar immunogenic properties are maintained in iPSC-derived lineage-committed cells (such as neural precursors) is relatively unknown. We demonstrate that syngeneic pig iPSC-derived neural precursor cell (NPC) transplantation to the spinal cord in the absence of immunosuppression is associated with long-term survival and neuronal and glial differentiation. No tumor formation was noted. Similar cell engraftment and differentiation were shown in spinaly injured transiently immunosuppressed swine leukocyte antigen (SLA)–mismatched allogeneic pigs. These data demonstrate that iPSC-NPCs can be grafted into syngeneic recipients in the absence of immunosuppression and that temporary immunosuppression is sufficient to induce long-term immune tolerance after NPC engraftment into spinaly injured allogeneic recipients. Collectively, our results show that iPSC-NPCs represent an alternative source of transplantable NPCs for the treatment of a variety of disorders affecting the spinal cord, including trauma, ischemia, or amyotrophic lateral sclerosis.

INTRODUCTION
The technology for generating induced pluripotent stem cells (iPSCs) (1, 2) has opened new possibilities for patient-specific cell therapy, in vitro disease modeling, and drug discovery. Although disease-specific iPSCs provide an excellent tool for studying the developmental pathology of human diseases in vitro (3, 4), the use of iPSCs for spinal cord autologous, syngeneic, or allogeneic transplantation has rarely been tested in large-animal models. The use of large-animal models that show similarities in spinal cord and central nervous system (CNS) anatomy and function with humans is necessary for advancing cell transplantation therapies using iPSC technology to a clinical setting.

Given the ethical issues related to the use of primates, pigs serve as an alternative model for preclinical experiments in regenerative medicine (5, 6). However, isolation of embryonic stem cells (ESCs) from pigs is difficult and not effective (7). Several groups reported successful generation of pig iPSCs, but the engraftment properties of autologous or syngeneic iPSC–derived neural precursors once grafted back into CNS were rarely explored (8–11). Therefore, we sought to test the immunogenicity and engraftment properties of iPSC-derived lineage-committed NPCs, which are expected to be free of pluripotent cell contaminants and, therefore, not form teratoma-like tumor masses.

Here, we analyze syngeneic transplantations of pig NPCs derived from swine leukocyte antigen (SLA)–inbred pig iPSCs. NPCs were isolated by manual clone selection, expanded, and characterized before transplantation. Three months after transplantation into the spinal cord of syngeneic recipients in the absence of immunosuppression, NPCs showed robust engraftment and neuronal/glial differentiation without detectable rejection or tumor formation. In addition, a comparable degree of cell engraftment and differentiation was observed after allogeneic transplantation in transiently immunosuppressed pigs with previous chronic spinal traumatic injury. No detectable presence of circulating anti–iPSC-NPC antibodies was seen in iPSC-NPC–grafted nonimmunosuppressed syngeneic or transiently immunosuppressed allogeneic pigs.

These data demonstrate the lack of immunogenicity of iPSC-NPCs engrafted into naive noninjured or spinal trauma–injured spinal cord. In addition, the successful engraftment observed in allogeneic animals receiving only time-limited immunosuppression indicates a potential for clinical utilization of human iPSC-NPCs in patients with a different human leukocyte antigen signature.
RESULTS

NPCs derived from reprogrammed adult porcine skin fibroblasts generate functional neurons in vitro

We first generated the porcine iPSC-NPCs. Four fully SLA-matched adult pigs were used to obtain skin biopsies (Fig. 1A). All tissue explants successfully produced fibroblasts (Fig. 1B) and pluripotent colonies (Fig. 1, C and D) after reprogramming using Sendai vectors (12) encoding octamer-binding transcription factor 4 (OCT4), (sex-determining region Y)–box 2 (SOX2), Kruppel-like factor 4 (KLF4), and myelocytomatosis viral oncogene (c-MYC). Expression of the pluripotent markers such as KLF4, SOX2, OCT4, and Nanog homeobox (NANOG) was seen in proliferating iPSC colonies (Fig. 1, E to H). Previously frozen iPSCs (passages 12 to 18) showed a comparable formation of pluripotent colonies and expression of pluripotent markers (fig. S1, A to F).

To test the differentiation potential of established iPSCs, three different in vitro or in vivo assays were used. First, proliferating colonies were induced to form embryoid bodies (EBs) (Fig. II) and continuously cultured in the presence of pig serum (0.1 to 1%) for 3 to 4 weeks. Second, a single monolayer of iPSCs was induced using established germ layer–specific (ectoderm, endoderm, or mesoderm) induction protocols for 10 to 14 days. After induction, EBs and induced iPSCs were stained with markers of mesoderm (smooth muscle actin and brachyury), endoderm (α-fetoprotein (AFP) and sex-determining region Y (SOX17)), and ectoderm (orthodenticle homeobox 2 (OTX2) and neuron-specific class III β-tubulin (TUJ1)). Third, a single cell suspension of iPSCs was injected into the testes of immunodeficient mice, and the presence of teratomas was analyzed at 4 to 8 weeks after injection. Staining of in vitro–induced EBs (fig. S1, G to J) or induced single cell–seeded iPSCs (fig. S1, K to M) shows the expression of definitive ectoderm, endoderm, and mesoderm markers. Macrosopic inspection of iPSC-injected testes showed extensive bilateral tumor formation at intervals longer than 5 weeks after cell injection (fig. S1N, left bottom, black-background inset). Hematoxylin and eosin (H&E) staining of histological sections taken from injected testes showed developed teratomas with all three germ layer derivatives (Fig. IJ and fig. S1N).

To generate NPCs, we cultured EBs in the presence of basic fibroblast growth factor (bFGF) to potentiate the formation of neural rosettes (Fig. 1K). NPCs were then manually harvested from the periphery of neural rosettes. NPCs were further expanded with bFGF as a sole mitogen (10 ng/ml) for up to 35 passages (Fig. 1L) with expression of neural precursor markers including SOX2, type VI intermediate filament protein (NESTIN), aniridia type II protein (PAX6), and SRY-box 1 (SOX1) (Fig. 1, M to P). Comparable neural precursor morphology in previously frozen and replated NPCs (passage 24) was also seen (fig. S2, A and B). Karyotype analysis using Giemsa banding (G-banding) demonstrated a stable karyotype in proliferating NPCs at passages 15 and 30 (fig. S2, C and D). Quantitative flow cytometry analysis showed 91 ± 14% of SOX1+ cells, 51.7 ± 12% of PAX6+, 90.8 ± 9% of SOX2+, and 72.3 ± 17% of NESTIN+ cells, respectively (fig. S2, E to J).

To characterize the multilineage potential of our iPSC-NPCs, we subcultured NPCs on an established human fetal astrocyte monolayer and then induced by withdrawal of bFGF and addition of cyclic adenosine monophosphate (cAMP), brain-derived neurotrophic factor (BDNF), and glial cell–derived neurotrophic factor (GDNF). The cultured NPCs were designed to express EGFP under the synapsin (SYN) promoter, and immunofluorescence staining of 8 week–induced NPCs showed multipolar EGFP+ neurons expressing doublecortin (DCX) and Fox-3 (NeuN) (Fig. 1, Q and R). A subpopulation of DCX+ neurons showed γ-aminobutyric acid (GABA) immunoreactivity (Fig. 1S). TUJ1 immunoreactivity was also seen (Fig. 1T). To assess the functionality of induced neurons in vitro, we measured spontaneous oscillation in cytosolic calcium (Ca2+) after loading the induced neurons with the Ca2+ indicator dye Fluo-4 AM. A consistent cyclical type of calcium oscillation lasting between 4.0 and 17.6 s, suggestive of neuronal depolarization, was observed in numerous neurons (Fig. 1U, white boxed regions). To characterize quantitatively the number of neuronal and glial cells that can be induced from iPSC-NPCs, we treated proliferating NPCs with 1% porcine serum for 20 days. Qualitative and quantitative analyses of induced NPCs showed effective differentiation to neurons (expressing the neuronal marker TUJ1), astrocytes (expressing the astrocyte marker glial fibrillary acidic protein (GFAP)), and glial and oligodendrocyte/precursors [expressing VIMENTIN, chondroitin sulphate proteoglycan 4 (NG2), and oligodendrocyte transcription factor (Olig2)] (fig. S2, K to N).

In vivo–transplanted iPSC-NPCs generate functional neurons at 7 to 10 months after grafting into striata of immunodeficient rats

We next tested the functionality of porcine iPSC-NPCs (SYN-EGFP-NPCs) after grafting into the striatum of adult immunodeficient rats (Fig. 2A). Animals (n = 12) received three bilateral injections of SYN-EGFP-NPCs (30,000 cells per injection; 2 μl per injection site) into the striatum. One to 10 months after cell grafting, we prepared ex vivo brain slices and performed patch-clamp recordings from SYN-EGFP+ grafted cells (Fig. 2B and fig. S3A). A subset (n = 6) of grafted animals was perfused with cold saline, and striata were harvested for mRNA sequencing (to analyze porcine-specific transcripts (n = 2; two individual NPC-grafted striata analyzed at 10 months after grafting) or fixed with 4% paraformaldehyde (n = 4; 7 months after grafting) and the grafted cells studied with immunofluorescence staining with neuron-specific antibodies [NeuN, neuron-specific enolase (NSE), DCX, SYN, vesicular GABA transporter (VGAT), gephyrin, and neurofilament (NF)]. A relative number (% of total EGFP+ neurons) of double-immunoreactive EGFP/DCX, EGFP/NeuN, and EGFP/NSE neurons was quantified using confocal microscopy (table S1).

Patch-clamp recording in EGFP+ neurons showed that all the examined transplanted cells (n = 3) showed properties of mature neurons, such as robust trains of action potentials (average = 18 Hz) in response to 500-ms depolarizing steps of currents (Fig. 2C), large voltage-gated sodium/potassium currents (Nav peak average = −5745 pA) (Fig. 2D), low resting membrane potentials (average = −78 mV), and spontaneous excitatory synaptic activity (table S2).

Immunofluorescence staining revealed numerous SYN-EGFP+ neurons with extensive processes in the grafted striatal regions (Fig. 2E). Confocal microscopy showed that virtually all SYN-EGFP+ cells colocalized with NeuN (Fig. 2E, insets, and fig. S3, A and B). Similarly, intense porcine-specific, NSE expression (13) was seen in EGFP+ grafts (Fig. 2F and fig. S3C). Staining with antibodies specific for SYN and/or VGAT showed a high density of SYN/EGFP+ or SYN/VGAT+ puncta on the soma/membranes of endogenous NeuN-positive neurons or EGFP+ grafted neurons (Fig. 2, G and H, and fig. S3D). Costaining with presynaptic inhibitory marker (VGAT) and postsynaptic glycine receptor marker (gephyrin) showed the presence of glycine receptors on grafted EGFP+ neurons in opposition to VGAT+ terminals (Fig. 2I, inset), suggesting the development of inhibitory glycinergic synaptic contacts.
Fig. 1. In vitro–differentiated porcine iPSC-derived neural precursors give rise to functional neurons.

(A) Schematic diagram of the experimental timeline and design in vitro and in vivo. EGFP, enhanced green fluorescent protein. (B to H) Cultured fibroblasts (B) formed colonies of pluripotent cells (Pluri. colonies) at 10 days after infection (C and D) and expressed pluripotent markers including KLF4 (E), SOX2 (F), OCT4 (G), and Nanog (H). (I) Established iPSC-derived EBs cultured in nonattachment culture flasks. (J) H&E staining of mouse testes at 6 weeks after injection of iPSCs suspended in Matrigel. Development of mature teratoma with identifiable all three germ layer derivatives including neural tube rosettes (1, ectoderm, red arrows; upper inset), smooth muscle (2, mesoderm, red arrows; middle inset), and gut cuboidal epithelium with goblet cells (3, endoderm, red arrows; lower inset) can be seen. (K and L) NPC colonies were manually harvested from the periphery of attached and induced EBs/neural rosettes (K) and further expanded (L). (M to P) Long-term expanded NPCs show expression of markers typical of neural precursors including SOX2 (M), PAX6 (N and P), SOX1 (O), and Nestin (N and O). DAPI, 4′,6-diamidino-2-phenylindole. (Q to T) Staining of induced SYN-EGFP-NPCs (R) with neuronal markers DCX (S and T), NeuN (S), and TuJ1 (U) was seen. A subpopulation of DCX+ neurons was GABA-immunoreactive (T). (U) Fluo-4 AM–loaded, 2 month–induced NPCs showing spontaneous intracellular calcium oscillation in axons (1, 1′) and neuronal soma (2, 2′ and 3, 3′). Scale bars, 500 μm (J), 10 μm (M), 15 μm (N), 10 μm (O), and 10 μm (S to U). a.u. arbitrary units.
Transplanted iPSC-NPCs are nontumorigenic and acquire genetic signature of mature porcine CNS at 7 to 10 months after grafting into striata of immunodeficient rats

We next performed whole-transcriptome mRNA-sequencing analysis on the striatum of immunodeficient rats that had received iPSC-NPC grafts (Fig. 3, A to D). Striatal tissue was harvested 10 months after iPSC-NPC grafting. To separate the pig mRNA sequence reads from the host rat mRNA reads, we developed a bioinformatics pipeline to sort mRNA sequence reads in a species-specific manner to either pigs or rats (Fig. 3E). Slight variations in the genome sequence between pigs and rats allowed us to differentiate between the species with a high sensitivity (99.52% efficiency). We detected 9332 pig genes expressed in the grafted rat striatum. This represented 5.19% of pig genes in the entire rat brain transcriptome.

Staining with NF antibody showed high-density NF neural processes within EGFP+ grafts (fig. S3E).
of the total mRNA reads from the graft tissue, with a false-positive sorting rate of 0.47% (appendix S1 and table S3). Gene expression was analyzed with t-distributed stochastic neighbor embedding (t-SNE) to determine the global gene expression patterns in the samples. Gene expression patterns from the transplanted iPSC-NPCs correlated strongly with the expression pattern of control mature pig CNS tissue, but not with the original iPSC-NPCs or iPSC populations (Fig. 3F). Analysis of mature CNS-specific transcripts in grafted cells shows high expression of neuronal markers and only moderate to low expression of glial genes (fig. S3, F and G). These data indicate that transplanted iPSC-NPCs differentiate normally into neuronal and glial subtypes and adopt gene expression patterns indicative of the environment into which they were grafted.

To identify any neuropathologically defined signs of tumor formation, we also stained sections using H&E. Consistent with immunofluorescence staining, well-incorporated grafts that fused with the host tissue were identified. No gross signs of tissue necrosis or aberrant tissue proliferation were noted (fig. S4A). Staining with myelin basic protein (MBP) and OLIG2 antibodies showed incomplete myelination in EGFP+ grafts, which was in contrast with the surrounding host tissue (fig. S4, B to D). In the same areas, the presence of VIMENTIN+ cells and oligodendrocytes (OLIG2+) was also seen, suggesting ongoing myelination (fig. S4, E to G).
Staining with endothelial marker Reca-1 showed regularly distributed vessel profiles in EGFP⁺ grafts (fig. S5, A and B). The expression of a subset of proto-oncogenes and tumor suppressor genes in grafted rat striata at 10 months after grafting was very similar to that observed in normal control pig spinal cord and striatum tissue (fig. S5C).

Collectively, these data show that we have generated a transplantable, nontumorigenic population of porcine iPSC-NPCs that shows a robust neuronal differentiation and is functional once grafted into the adult CNS of immunodeficient rats.

Syngeneic porcine iPSC-NPCs grafted spinaly in adult naïve pigs show long-term survival in the absence of immunosuppression

We next tested whether the syngeneic transplantation of porcine iPSC-NPCs into the lumbar spinal cord of naïve noninjured pigs would support cell survival in the absence of immunosuppression. Three SLA fully matched minipigs received 20 bilateral syngeneic grafts of iPSC-NPCs (SYN-EGFP⁺) targeted into the central gray matter of the L2–L5 spinal cord segments (50,000 live cells/µl, 10 µl per injection). Three months after grafting, the animals were sacrificed and the spinal cord was harvested for subsequent analysis.

Immunofluorescence analysis of horizontal spinal cord sections throughout the grafted region showed the presence of long bilateral EGFP⁺ grafts extending for more than 2 cm (Fig. 4A and fig. S6A). No tumor formation or aberrant tissue mass was seen in any animal. High-density NF-positive and GFAP-positive networks were identified in EGFP⁺ grafts (Fig. 4, B and C, and fig. S6, B and C). Staining with neuron-specific markers including DCX, NeuN, and NSE showed neurons that occupied the entire EGFP⁺ grafts (Fig. 4, D to F, and fig. S6, D to F). Analysis of axonal projections into regions caudal and cranial from the border of the EGFP⁺ graft showed the projection of EGFP⁺ axons for distances longer than 2 to 3 cm. These axons showed coexpression of NF (Fig. 4, G to I). A quantitative analysis (% of total EGFP⁺ neurons) of double-immunoreactive EGFP/DCX, EGFP/NeuN, and EGFP/NSE neurons is presented in table S1.

Staining with the SYN antibody revealed a high density of SYN⁺ puncta throughout the EGFP⁺ graft (fig. S6G). The majority of the EGFP⁺/SYN⁺ puncta displayed colocalization with VGAT and was opposed to postsynaptic gephyrin⁺ puncta found on EGFP⁺ grafted neurons or EGFP-negative host neurons (Fig. 4, J and K, and fig. S6G). These data demonstrate the development of putative inhibitory synaptic contacts.

Syngeneic pigs receiving spinal iPSC-NPCs grafts show no humoral immunity against grafted cells at 3 months after cell transplantation

To test for the presence of circulating anti-iPSC-NPC antibodies in syngeneic pigs grafted spinaly with iPSC-NPCs, a combined in vivo and ex vivo immunostaining assay was developed. First, a homogenate and ex vivo immunostaining assay was developed. First, a homogenate was prepared from the grafted area. The homogenate was then injected into the grafted area. The grafted area was then harvested and stained using the sera taken from immunized pigs (positive control), naive nonimmunized allogeneic pig (negative control), and syngeneic pigs that had previously received spinal iPSC-NPC-EGFP grafts.
of double-immunoreactive EGFP/DCX, EGFP/NeuN, EGFP/NSE, EGFP/GFAP, and EGFP/OLIG2 neurons and glial cells is presented in table S1.

The H&E staining showed well-incorporated individual grafts with morphology consistent with mature neural tissue (fig. S9A). In comparison with the host surrounding tissue, incomplete myelinization was observed, as evidenced by a low density of MBP immunoreactivity within EGFP+ grafts (fig. S9, B and C). Numerous triple-stained EGFP/VIMENTIN/Ki67+ cells were found within EGFP+ grafts [fig. S9, D (insets) and E]. These data suggest ongoing myelinization and proliferation of glial precursors. To study the dynamics of cell proliferation (Ki67+ cells) in developing porcine spinal cord, we next stained spinal cord sections prepared from 70-day-old porcine fetus (gestational period in pig is around 115 days), newborn piglet, and adult naïve pig (18 months old). In the 70-day-old fetus, a high density of Ki67+ cells in both white and gray matter regions was seen.
The number of Ki67+ cells decreased in newborn piglets but was still present in the adult pig (fig. S9, F to I). These data are consistent with a previous report in mice that demonstrated an ongoing proliferation of glial precursors in the intact adult spinal cord (16).

Next, we tested the presence of circulating antibodies against iPSC-NPCs by staining mature (6 months after grafting) iPSC-NPC grafts in the rat striata with sera harvested from allogeneic iPSC-NPC-grafted pigs. In contrast to the strong staining observed with sera from anti-iPSC-NPC-immunized pig, no staining was detected with sera from allogeneic graft recipients (Fig. 6, O and P). As shown in table S4 (A and B), the SLA genotypes of the iPSC-NPC donor and the allogeneic graft recipients were well mismatched at both the antigen (allele group) and allele level across the class I (SLA-1, SLA-2, and SLA-3) and class II (DRB1, DQA, and DQB1) loci tested (17–23).

To further probe for the presence of an immune response in cell-grafted spinal cord regions, we stained spinal sections with porcine-specific anti-major histocompatibility complex II (MHC-II), CD45 (leukocyte common antigen), CD8 (coreceptor for the T cell receptor), and ionized calcium-binding adapter molecule 1 (Iba1; microglial marker) antibodies. Sections were taken from the following: (i) spinal cord of syngeneic pigs 3 months after iPSC-NPC grafting without immunosuppression; (ii) spinal cord of injured, continuously immunosuppressed allogeneic pigs 4 weeks after iPSC-NPC grafting; and (iii) spinal cord of injured, transiently immunosuppressed allogeneic pigs 3.5 months after iPSC-NPC grafting. In syngeneic pigs, the staining with anti–MHC-II antibody showed that the immunoreactivity was restricted around the needle injection tracts (Fig. 7A). In allogeneic spinally injured animals with continuous or transient immunosuppression, a more diffuse staining pattern was seen, and MHC-II+ cells were observed throughout the EGFP+ graft as well as in surrounding injured host tissue (Fig. 7, B and C). Staining with Iba1 antibody exhibited a very similar staining pattern as was seen for MHC-II staining (Fig. 7A). In allogeneic spinally injured animals with continuous or transient immunosuppression, a more diffuse staining pattern was seen, and MHC-II+ cells were observed throughout the EGFP+ graft as well as in surrounding injured host tissue (Fig. 7, B and C). Staining with CD45 and CD8 antibodies showed accumulation of both cell types around the cell injection tract in syngeneic pigs and more diffuse presence of CD45/CD8-positive cells in allogeneic spinally injured pigs with continuous or transient immunosuppression (Fig. 7, D to F). Analysis of double MHC-II– and Iba1-stained sections showed that virtually all MHC-II+ cells expressed Iba1 (Fig. 7J). Quantitative comparative analysis of CD45- and CD8-positive cells between allogeneic spinally injured continuously immunosuppressed animals (1-month postgrafting survival)
and animals with transient immunosuppression 3 months after grafting showed a significant decrease in the number of both CD45+ and CD8+ cells 3 months after cell grafting in transiently immunosuppressed animals (Fig. 7, K and L).

These data demonstrate that spinal grafting of iPSC-NPCs in syngeneic nonimmunosuppressed or allogeneic transiently immunosuppressed animals leads to a robust graft survival with minimal immune response at the site of cell grafting.
Fig. 7. Transient immunosuppression (4 weeks) supports long-term graft survival and is associated with progressive decrease in spinal regional inflammatory response in iPSC-NPC–grafted spinally injured allogeneic pig. (A to C) Immunofluorescence staining for MHC-II and EGFP around cell injection needle tract in syngeneic pigs (A; n = 3) and in allogeneic continuously immunosuppressed (B; n = 3) or transiently immunosuppressed (C; n = 3) spinally injured pigs 4 weeks or 3.5 months after cell grafting. (D to F) Immunofluorescence staining for Iba1 and EGFP around cell injection needle tract in syngeneic pigs (D) and in allogeneic continuously immunosuppressed (E) or transiently immunosuppressed (F) spinally injured pigs 4 weeks or 3.5 months after cell grafting. (G to I) Immunofluorescence staining for CD45, CD8, and EGFP around cell injection needle tract in syngeneic pigs (G) and in allogeneic continuously immunosuppressed (H) or transiently immunosuppressed (I) spinally injured pigs 4 weeks or 3.5 months after cell grafting. (J) Colocalization of MHC-II with Iba1 in the core of the graft. (K and L) Quantitative analysis of CD45+ and CD8+ leukocytes in EGFP+ grafts and in surrounding host tissue (Student’s t test; *** P < 0.05). Scale bars, 300 μm (A to C and G to I), 20 μm (D to F), and 10 μm (J).
Analysis of neurological function in allogeneic NPC-grafted animals 3.5 months after grafting was performed using a previously developed porcine neurological scale designed to quantify the loss of motor function after spinal cord traumatic injury in adult pigs (24). Grade “0” corresponds with complete paraplegia with no detectable movement in the hindlimbs, and grade “14” corresponds with normal ambulatory function. NPC-grafted animals showed 2 to 3 degrees improvement (from grade 6 to grade 8 or 9) compared to pretransplantation baseline. This corresponds to better movement in all three joints of lower extremities but with no ability to support weight or walk.

**Reprogramming factors and immunogenic genes are not expressed in vivo inrafted iPSC-NPCs**

We next studied the residual protein expression of reprogramming factors (OCT4, KLF4, and SOX2) and Sendai virus–associated protein (SeV) in grafted cells at 3 and 7 months after grafting by using sections taken from grafted rat striata and allogeneic pig spinal cord. Sections were also stained with Ki67 antibody. Staining with OCT4 and KLF4 antibodies showed no residual staining in grafted cells (fig. S10, A to H). Staining with SOX2 antibody showed regularly distributed SOX2+ cells within EGFP+ grafts in both rat striata and allogeneic pig spinal cord (fig. S10, I to L). In allogeneic pig spinal cord, a specific SOX2 expression was also seen in endogenous ependymal cells of central canal (fig. S10L, white dotted line). Staining with Ki67 antibody showed regularly distributed double EGFP/Ki67-stained cells in both rat striata and allogeneic pig spinal cord grafts (fig. S10, M to P). Staining with anti-SeV antibody revealed only occasional presence of Sendai virus–associated protein in grafted EGFP+ cells (fig. S11, A to D). The mRNA-sequencing analysis showed no apparent differences in several immunogenic genes including Hormad1 and Cyp39A1 (fig. S11E).

**DISCUSSION**

Using nonintegrating Sendai virus (encoding OCT4, SOX2, KLF4, and c-MYC), we demonstrated the successful reprogramming of porcine skin fibroblasts harvested from adult fully SLA-matched pigs to iPSCs. After iPSC induction, we isolated the NPCs by manual selection and expanded for more than 20 passages while maintaining a stable karyotype and expressing markers typical of NPCs (such as SOX1, SOX2, NESTIN, and PAX6). Once grafted into the striata of immunodeficient rats or the spinal cord of syngeneic naïve nondamaged pigs in the absence of immunosuppression, NPCs differentiated into functional neurons and glial cells (astrocytes and oligodendrocytes). Consistent with an advanced stage of grafted NPC maturation, the mRNA-sequencing analysis of porcine-specific transcripts in rat striata at 10 months after grafting showed a pattern of expression similar to control mature pig CNS tissue. Moreover, long-term survival of iPSC-NPC–derived cells was observed after grafting into spinal cord–injured allogenic pigs that had received only transient immunosuppression.

A previous study has reported immunogenicity from syngeneic mouse iPSCs upon transplantation that may be related to an ongoing overexpression of pluripotent genes (25). In addition, several other factors such as expression of virus-related proteins generated by episomal vectors used for reprogramming and the MHC expression in specific iPSC derivatives may contribute to overall immunogenicity of transplanted cells (25). We have addressed those issues and have demonstrated that (i) there is no expression of pluripotent genes at 3 to 7 months after transplantation and (ii) only occasional Sendai virus–associated protein was present in grafted iPSC-NPCs. These data suggest that, although a residual Sendai viral protein is present at the moment of grafting, it is not sufficient to trigger hyperacute or late T cell–mediated rejection. We have also demonstrated a lack of humoral or cellular response in syngeneic and allogeneic pigs receiving iPSC-NPC grafts. These data further demonstrate that even a mature iPSC-NPC graft does not express antigens that would be sufficient to initiate an immune response at prolonged periods after grafting.

In addition, there are several other variables that we believe need to be considered while generating iPSC-derived transplantable cell lines for experimental or clinical application. It has been demonstrated that several genes are expressed at abnormally high levels in mouse iPSCs. A subset of up-regulated genes with known immunogenic properties, including Hormad1, Zg16, and Cyp3a11, has been found to be directly linked to the T cell–mediated rejection of teratomas that formed after grafting of mouse iPSC lines into syngeneic recipients (25). All the iPSCs used in this previous study (13) came from fetal fibroblasts, an unlikely source for future therapies in humans, and the gene expression changes may be related to epigenetic memory of this specific developmental time. The use of adult fibroblasts in our current experiments may contribute to the lack of immunogenic gene up-regulation.

Altered gene expression can also be due to the transcriptional memory observed in iPSCs (26, 27) or caused by somatic alterations in protein-coding regions accumulated in these cells (28). Whether there is increased activity of potentially immunogenic proteins in long-term expanded iPSC-derived cell lines is not defined at present. Thus, a periodic analysis of such changes needs to be performed to assure consistency of the genetic profile across specific lots of transplantable cells.

We have previously demonstrated that culturing human ESCs in the presence of animal components, such as mouse feeder cells or bovine albumin, leads to the incorporation of animal molecules in the membranes of human cells (29). These molecules, such as N-glycolylneuraminic acid (Neu5Gc), contaminated human ESCs and initiated an antibody-mediated complement deposition when the cells were exposed to human sera. Accordingly, in our current study, to avoid the contamination of generated iPSCs by nonporcine animal component(s), we have used porcine fetal skin–derived fibroblasts as a feeder layer, and no serum derived from other animal species was used. Thus, the derived iPSC-NPCs had no nonporcine elements in their membranes that can elicit an immune reaction in the syngeneic or allogeneic graft recipients.

Previous studies reported the transplantation of iPSC-derived dopaminergic precursors using intrastriatal autologous or allogeneic grafting in nonhuman primates without immunosuppression (30, 31). Minimal or no immune response was seen in autologous grafts, whereas a progressive acquired immune response was seen in allogeneic graft recipients at 3.5 to 4 months after cell grafting. We show that the transient immunosuppression protocol used in our current study is effective in inducing a long-term graft tolerance in allogeneic spinally injured and SLA-mismatched recipients. These results are similar to our previously reported data that demonstrate tolerance across a two-haplotype, fully MHC–mismatched barrier in miniature swine renal allografts after transient (12 days) high-dose treatment with tacrolimus (32). More recently, a functional engraftment of allogeneic iPSC–derived cardiomyocytes after a direct...
intramyocardial injection in the cynomolgus monkey model of myocardial infarction was reported. In this experiment, continuous immunosuppression with tacrolimus was used (33). Other groups have reported on the functional benefit after spinal grafting of human iPSC-NPCs in mouse and marmoset spinal injury models (34, 35) and also demonstrated low immunogenicity of mouse iPSC-NPCs (36, 37).

Because the spinal cord and brain represent sites of immune privilege, it has long been speculated that only transient immune suppression is sufficient to ensure long-term engraftment of human fetal tissue–derived or iPSC-NPCs in human allogeneic graft recipients. Thus, our findings demonstrate in a large-animal model of spinal cord traumatic injury that, in fact, a transient 4-week immunosuppression is effective in inducing immune tolerance against allogeneic iPSC-NPC grafts. One limitation of our current study is that a relatively short postgrafting period of survival was used in the pig component of the study. Accordingly, a prolonged post-grafting survival likely exceeding 1 year will be needed to confirm a permanent iPSC-NPC engraftment once cells are grafted into syngeneic or allogeneic transiently immunosuppressed recipients.

Our preclinical large-animal model system will allow us to establish prospective assays to predict graft rejection in the context of autologous, syngeneic, or allogeneic grafting of iPSC-derived neural precursors in naïve or previously injured spinal cord. Similar to the studies from Zhao et al. (25), we expect that a profiling of gene regulation, membrane-bound, and soluble-releasable proteins that have immunogenic properties, and recipient T cell activation assays, will be important in determining the immunogenicity of prospective iPSC-derived lineage–committed cell lines to be used for in vivo grafting. In this manner, the degree of immunosuppression could be personalized to the quantity of recipient T cell reactivity to graft antigens, thereby ensuring that appropriate immune suppression is used.

MATERIAL AND METHODS
Study design
This study was designed to characterize the survival of porcine iPSC-NPCs after spinal grafting in adult naïve syngeneic (nonimmunosuppressed) or chronic spinoally injured allogeneic (transiently immunosuppressed) pigs. To generate pluripotent cells, we used Sendai virus encoding four reprogramming factors to reprogram adult pig fibroblasts (harvested from inbred SLA-matched pigs) in vitro. The pluripotent nature of established iPSC colonies was determined by in vitro induction into all three germ layers (ectoderm, mesoderm, and endoderm) and by the formation of in vivo teratoma. NPC were then induced from pluripotent colonies using the NSC induction protocol and established NPC was characterized in vitro and in vivo by the following: (i) expression of NPC markers (flow cytometry or indirect immunofluorescence), (ii) ability of neurons to spontaneously depolarize after long-term in vitro induction (Ca2+ oscillation), and (iii) ability of iPSC-derived neurons to generate action potential in ex vivo striatal slices. To study a multipotent potential of established iPSC-NPCs (SYN-EGFP) grafted into rat striata, we used immunofluorescence staining using neuronal and glial markers and mRNA sequencing using bioinformatics protocol that separates the pig mRNA sequence reads from the host rat mRNA reads. Neurotransmitter phenotype of grafted iPSC-NPC–derived neurons was studied in EGFP+ grafts in rat striata and pig spinal cord by immunofluorescence staining with pre- and postsynaptic markers specific for inhibitory or excitatory neuronal phenotype.

For quantitative analysis of immune response markers (CD45 and CD8), spinal cord sections taken from iPSC-NPC–grafted (i) syngeneic pigs, (ii) allogeneic pigs at the end of 4 weeks immunosuppression, and (iii) allogeneic pigs at 2.5 months after immunosuppression was terminated, were used. The presence of positively stained CD45 and CD8 cells was analyzed separately in the EGFP+ grafts and in surrounding host tissue.

Full details on the methods of in vitro iPSC and iPSC-NPC generation/characterization and in vivo iPSC-NPC grafting and postmortem analysis can be found in the Supplementary Materials.

Statistical analysis
For statistical analysis, the number of positively stained (CD45+ and CD8+) cells in allogeneic animals (pigs) with continuous and transient immunosuppression was compared using unpaired, two-tailed Student’s t test for single comparisons. Data were considered significantly different if P < 0.05. GraphPad Prism software was used to run Student’s t test.

BONE

Mechanobiologically Optimized 3D Titanium-Mesh Scaffolds Enhance Bone Regeneration in Critical Segmental Defects in Sheep

Anne-Marie Pobloth et al.

Three-dimensional (3D) titanium-mesh scaffolds offer many advantages over autologous bone grafting for the regeneration of challenging large segmental bone defects. Our study supports the hypothesis that endogenous bone defect regeneration can be promoted by mechanobiologically optimized Ti-mesh scaffolds. Using finite element techniques, two mechanically distinct Ti-mesh scaffolds were designed in a honeycomb-like configuration to minimize stress shielding while ensuring resistance against mechanical failure. Scaffold stiffness was altered through small changes in the strut diameter only. Honeycombs were aligned to form three differently oriented channels (axial, perpendicular, and tilted) to guide the bone regeneration process. The soft scaffold (0.84 GPa stiffness) and a 3.5-fold stiffer scaffold (2.88 GPa) were tested in a critical size bone defect model in vivo in sheep. To verify that local scaffold stiffness could enhance healing, defects were stabilized with either a common locking compression plate that allowed dynamic loading of the 4-cm defect or a rigid custom-made plate that mechanically shielded the defect. Lower stress shielding led to earlier defect bridging, increased endochondral bone formation, and advanced bony regeneration of the critical size defect. This study demonstrates that mechanobiological optimization of 3D additive manufactured Ti-mesh scaffolds can enhance bone regeneration in a translational large animal study.

CELL ENGINEERING

Synthetic Biology-Based Cellular Biomedical Tattoo for Detection of Hypercalcemia Associated with Cancer

Aizhan Tastanova et al.

Diagnosis marks the beginning of any successful therapy. Because many medical conditions progress asymptomatically over extended periods of time, their timely diagnosis remains difficult, and this adversely affects patient prognosis. Focusing on hypercalcemia associated with cancer, we aimed to develop a synthetic biology-inspired biomedical tattoo using engineered cells that would (i) monitor long-term blood calcium concentration, (ii) detect onset of mild hypercalcemia, and (iii) respond via subcutaneous accumulation of the black pigment melanin to form a visible tattoo. For this purpose, we designed cells containing an ectopically expressed calcium-sensing receptor rewired to a synthetic signaling cascade that activates expression of transgenic tyrosinase, which produces melanin in response to persistently increased blood Ca2+. We confirmed that the melanin-generated color change produced by this biomedical tattoo could be detected with the naked eye and optically quantified. The system was validated in wild-type mice bearing subcutaneously implanted encapsulated engineered cells. All animals inoculated with hypercalcemic breast and colon adenocarcinoma cells developed tattoos, whereas no tattoos were seen in animals inoculated with normocalcemic tumor cells. All tumor-bearing animals remained asymptomatic throughout the 38-day experimental period. Although hypercalcemia is also associated with other pathologies, our findings demonstrate that it is possible to detect hypercalcemia associated with cancer in murine models using this cell-based diagnostic strategy.
TISSUE ENGINEERING

Computational Modeling Guides Tissue Engineered Heart Valve Design for Long-Term in Vivo Performance in a Translational Sheep Model

Maximilian Y. Emmert et al.

Valvular heart disease is a major cause of morbidity and mortality worldwide. Current heart valve prostheses have considerable clinical limitations due to their artificial, nonliving nature without regenerative capacity. To overcome these limitations, heart valve tissue engineering (TE) aiming to develop living, native-like heart valves with self-repair, remodeling, and regeneration capacity has been suggested as next-generation technology. A major roadblock to clinically relevant, safe, and robust TE solutions has been the high complexity and variability inherent to bioengineering approaches that rely on cell-driven tissue remodeling. For heart valve TE, this has limited long-term performance in vivo because of uncontrolled tissue remodeling phenomena, such as valve leaflet shortening, which often translates into valve failure regardless of the bioengineering methodology used to develop the implant. We tested the hypothesis that integration of a computationally inspired heart valve design into our TE methodologies could guide tissue remodeling toward long-term functionality in tissue-engineered heart valves (TEHVs). In a clinically and regulatory relevant sheep model, TEHVs implanted as pulmonary valve replacements using minimally invasive techniques were monitored for 1 year via multimodal in vivo imaging and comprehensive tissue remodeling assessments. TEHVs exhibited good preserved long-term in vivo performance and remodeling comparable to native heart valves, as predicted by and consistent with computational modeling. TEHV failure could be predicted for nonphysiological pressure loading. Beyond previous studies, this work suggests the relevance of an integrated in silico, in vitro, and in vivo bioengineering approach as a basis for the safe and efficient clinical translation of TEHVs.

TISSUE ENGINEERING

Production and Transplantation of Bioengineered Lung into a Large Animal Model

Joan E. Nichols et al.

The inability to produce perfusable microvasculature networks capable of supporting tissue survival and of withstanding physiological pressures without leakage is a fundamental problem facing the field of tissue engineering. Microvasculature is critically important for production of bioengineered lung (BEL), which requires systemic circulation to support tissue survival and coordination of circulatory and respiratory systems to ensure proper gas exchange. To advance our understanding of vascularization after bioengineered organ transplantation we produced and transplanted BEL without creation of a pulmonary artery anastomosis in a porcine model. While in bioreactor culture, we facilitated systemic vessel development using growth factor-loaded microparticles. A single pneumonectomy, performed one month prior to BEL implantation, provided the source of autologous cells used to bioengineer the organ on an acellular lung scaffold. During 30 days of bioreactor culture we facilitated systemic vessel development using growth factor-loaded microparticles. We evaluated recipient survival, autograft (BEL) vascular and parenchymal tissue development, graft rejection, and microbiome reestablishment in autografted animals 10 hours, 2 weeks, 1 month and 2 months after transplant. BEL became well vascularized as early as 2 weeks post-transplant and formation of alveolar tissue was observed in all animals (n = 4). There was no indication of transplant rejection. BEL continued to develop post-transplant and did not require addition of exogenous growth factors to drive cell proliferation or lung and vascular tissue development. The sterile BEL was seeded and colonized by the bacterial community of the native lung.
